

ABSTRACT

It is a distinct advantage to have predictable real-time data against which to compare the behavior of new real-time programs. The following report describes a system used to check out programs written to decommute and process telemetry (TM) data in real-time. Although the system is admittedly special purpose, it is believed that the principles used may have wide application in real-time simulation.

The system hardware consists of a general purpose digital computer with interrupt hardware, a TM data processor, and an inexpensive interrupt control and interface buffer. System software consists of a real-time TM data monitor and a conversational-mode interpreter used to construct data lists. In use, the telemetry data is generated by the computer and "transmitted" to the TM processor via the interface.

A SOFTWARE PACKAGE FOR REAL-TIME SIMULATION

Rationale & Problem Description

Real-time program check out can proceed only to a certain point before applying real-time constraints. Depending on a number of factors, this point can range from very early to very late in the debugging process. Usually the most critical portions of the program reside in that portion which requires a real-time situation similar to the real-time specifications of the program, to adequately verify that the program is working as intended. This is particularly true where the program is processing incoming data which is entering at a fixed but uncontrolled rate (i.e., uncontrolled by the program) and output equipment is slow compared to the input rate.

A particular example of such a program is one designed to decommute and process telemetered data which is in the form of a serial bit stream. Such a program was written for the Apollo Lunar Surface Experiments Package (ALSEP). Specifically, the program (actually a group of programs) is required to acquire sync, decommute, process, and output data to a very high speed line printer, or a digital-to-analog converter. In ALSEP, data is generated, converted to digital form and commutated before transmission. Some of this data is sub-commutated to as many as three lower levels. Implied in these statements is the presence of a sync-code for each commutation or "frame". Total synchronization was quite complex.

The programming assignment was eased somewhat by the use of a fairly advanced telemetry data processor. However, since it was a new

machine and the programming staff initially unfamiliar with its operation, adequate debugging aids became proportionally more important.

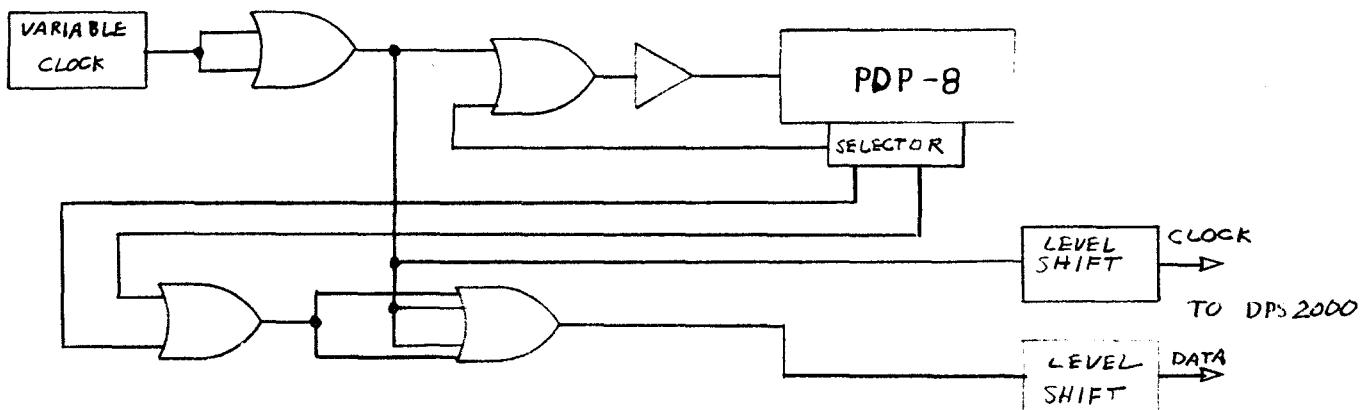

Due to the imposed bit rates, the required processing and the available hardware and software, a real-time operating system was written. This included a real-time input/output executive, subroutines for acquiring main frame sync, arithmetic processes, and printing. The total ALSEP telemetry format was partitioned into its experiments. A program was written for each experiment; that program was responsible for sync acquisition and processing peculiar to that experiment.

It became apparent fairly early in the project that some means to accurately simulate the ALSEP data format was needed. It was determined that these needs could best be fulfilled by using a small general purpose computer with interrupt hardware and a simple interrupt control/interface buffer. A software package was written for the simulating computer. It is this package that is the major topic of this report.

BASIC STRUCTURE

HARDWARE

1. Telemetry Data Processor: DPS 2000, manufactured by Bendix Electrodynamics Division. This is a special purpose digital computer with a section devoted entirely to telemetry sync acquisition and decommutation. The instruction set is divided about equally among TM and typical data processing commands. The particular version used has a 32 bit word, 4K magnetic core storage and a $2 \mu s$ cycle time. It is capable of handling TM bit rates of up to 10^6 B. P. S. I/O equipment consists of a 15 cps typewriter, a 6000 LPM line printer and a 300 cps paper tape reader. There was also an eight channel D to A converter feeding a corresponding strip chart recorder.
2. Simulating Computer: PDP-8, manufactured by Digital Equipment Corporation. This is a 12 bit, 4K machine with a $1.5 \mu s$ cycle time. The I/O configuration consisted of an ASR 33 teletype only.
3. Interrupt Control/Interface Buffer: The circuit is shown below.

SOFTWARE

1. Monitor: The purpose of this program is to thread through data lists and set up a waiting buffer from which an interrupt routine can draw data in real-time for output to the telemetry processor. The monitor is also capable of modifying the data stream in real-time via the teletype as the data is loaded into the waiting buffer. These modifications consist of (1) permanent changes to any part of the data, (2) temporary changes to any part of the data, (3) temporary changes to the main frame sync code, (4) addition of bits to the main frame for one MF time only, and (5) deletion of bits from the main frame for one MF time only. The monitor is capable of subframing to any level within core storage constraints. It is capable of handling fixed data, incrementing or decrementing count data, and random data. It can accommodate word lengths from 1 to 10 bits and has provision for three "special cases" (e.g., parity computation for a specific sub-set of words in the main frame list).

2. Interpreter: The purpose of this program is to construct the data lists used with the monitor. This is a conversational-mode program that interprets user responses to computer-generated requests for information and punches a binary paper tape which can be loaded into the PDP-8 along with the monitor. It sets up the data lists to be used by the monitor. It has provision for decimal or octal data input, and multiple addressing of a given subframe list. Certain shortcuts are available for inputting data. There is an error recovery facility available for the convenience of the user. Upon completing the input of data, the data lists are punched on paper tape in binary, with a checksum. Frame headers, counter addresses, and the data lists are printed.

SIMULATOR THEORY & IMPLEMENTATION

The algorithm used in the simulation treated the test data as if it were actually being commutated. The data is arranged in circular lists, each list having a pointer (or commutator arm to extend the analogy). Since ten bits was a convenient maximum simulator word size, two bits remain unused in the PDP-8 word. These two bits are used as flag bits to inform the monitor that the list position being presently examined is a switch to a lower level of commutation.

Since it was desired to have various types of data, as many as three special cases, and various word sizes from 1 to 10 bits, it was necessary to carry a descriptor word along with each data word. This is where maximum core economy had to be exercised. Without any effort to pack information efficiently, the total ALSEP simulator data would have occupied nearly all

the available core, leaving virtually no room for the monitor. Each descriptor word was therefore cut to 6 bits; two for special cases, two for data type, and two for word size. To accommodate a bit count from 1 to 10 the following approach was taken. The two word size bits are tested for zero. If they are not zero, 7 is added to give the size of the current word. If they are equal to zero, bits 2^9 , 2^8 , 2^7 of the data word are extracted and right justified to become the current word size. Data type flags are used to switch control to the appropriate routine. Count data in the data list consists of a low core base address where the pointer, IP & RP are stored. Random data is generated and the appropriate number of bits extracted as data.

Alternating waiting buffers are used to allow the output routine to draw its data from a completely filled buffer. These buffers each accommodate one main frame. Data for the next main frame is always being generated by the list processor. When the next frame is complete, control transfers to an idle loop. At the completion of the "transmission" of the current frame, the buffers are switched and the construction of the following frame is started.

SOFTWARE DETAIL

Monitor:

The monitor may be divided into three logically distinct sections:

(1) A list processing routine: The prime function is to thread through the data lists, constructing a main frame list in one of two alternating buffers for later output.

(2) An interrupt service routine (ISR) including output routine: The prime function of the ISR is to respond to an interrupt, and identify it as an interface, TTY input, or TTY output interrupt, and route program control to the appropriate routine. The output routine sequences through the appropriate buffer, "transmitting" one bit of data per interrupt.

(3) A real-time modifications routine controls the execution of modifications via TTY commands.

A commented assembly listing follows.

Interpreter:

The interpreter may be divided into three logically distinct sections:

(1) A data list building section which operates in a conversational or question-and-answer mode. In this section data is inputted to the PDP-8 by the user via the teletype. When a data word is specified it is stored in appropriate locations. Frame list storage is automatically allocated. Control of the builder section is retained by this section until all of the data words have been accounted for. At that point control is passed to the output portion of the program which contains the remaining two sections.

(2) A punch section which punches a binary tape of the main frame description, counters and the data lists. A second block of data is punched which consists of some important registers used by the interpreter. These registers, when loaded over the interpreter, offer the user a convenient restart procedure.

(3) A dump section which lists the sizes and header locations of each frame list, a dump of the counters, and a dump of the data lists.

A commented assembly listing follows.
