

MEASUREMENTS OF COSMIC RAY PRODUCED  $^{53}\text{Mn}$  AND  $^{10}\text{Be}$  IN LUNAR CORES.

K. Nishiizumi, J. R. Arnold, Dept. of Chemistry, B-017, Univ. of Calif., San Diego, La Jolla, CA 92093; D. Elmore, L. E. Tubbs, G. Cole and D. Newman, Nucl. Structure Lab., Univ. of Rochester, Rochester, NY 14627.

We have measured cosmic ray produced  $^{53}\text{Mn}$  ( $t_{1/2} = 3.7$  My) in double drive tube 64002 for the continuing study of lunar surface regolith mixing. We have also measured  $^{10}\text{Be}$  ( $t_{1/2} = 1.6$  My) in the Apollo 15 long core for study of the galactic cosmic ray (GCR) production profile using accelerator mass spectrometry.

$^{53}\text{Mn}$ . Core 64002/1 was collected at Stone Mountain on a  $16^\circ$  slope [1]. This is the steepest slope we have ever measured  $^{53}\text{Mn}$  profiles in. Core 64002 which is 26.4 cm in length and had a density of  $1.65 \text{ g/cm}^3$  after extrusion, is the top half of double drive tube 64002/64001. 64002 includes five stratigraphic units [1]. We have received 12 samples covering all five units. Before dissolution we examined the sample microscopically. Half the samples included small metallic grains, whose diameters ranged from 100 to 500  $\mu\text{m}$ . Several large metallic grains were separated from bulk soil for further studies. The preliminary SEM study shows a few metallic grains composed of almost pure Fe, S, Ni and P. Goldstein and Axon [2] have found high Fe, Ni, P, Co and S content in metallic particles from three Apollo 16 soils.

The preliminary  $^{53}\text{Mn}$  contents of 64002 are shown in Fig. 1. The  $^{53}\text{Mn}$  profile for the top 20-25  $\text{g/cm}^2$  is rather flat and higher than the Reedy-Arnold calculated curve. The integral of apparent SCR (Solar Cosmic Ray)  $^{53}\text{Mn}$  down to 25  $\text{g/cm}^2$  is higher by 40-45%. Activity levels fall to the Reedy-Arnold GCR production line [3] below 25  $\text{g/cm}^2$ . A textural boundary at 26  $\text{g/cm}^2$  [1] matches this result. The high and flat  $^{53}\text{Mn}$  profile above 20  $\text{g/cm}^2$  strongly indicates that this surface soil was recently deposited on this site over a short period. If we assume sudden deposition, such an event happened about 1.5-3 My ago and this soil was well-exposed to cosmic rays above  $\sim 4 \text{ g/cm}^2$  depth before deposition. This time is consistent with the 2 My so-called South Ray Crater event. Many rock samples collected at station 0, 4, 6, 8 and 9 have about a 2 My exposure [4], especially 64435 and 64455 which were collected about 10 m distant from core 64002/1 [5]. However, rare gas [4,6], track [7] and FMR [8] studies of all soil samples collected at these stations indicate those soils were well-irradiated,  $\sim 100$  My, and mature. From these studies and this  $^{53}\text{Mn}$  measurement, we conclude that either (1) surface soil samples at station 4 are not South Ray Crater materials, or (2) South Ray Crater is much older than 2 million years. This intriguing puzzle requires more measurements to resolve it.

$^{10}\text{Be}$ . Three samples of  $^{10}\text{Be}$  in the Apollo 15 drill core were measured by accelerator mass spectrometry using the Rochester MP Tandem Van de Graaff. We have measured  $^{10}\text{Be}/^9\text{Be}$  ratios of  $2-6 \times 10^{-12}$  ( $\sim 4-10 \times 10^{-4}$  dpm  $^{10}\text{Be}$ ) with better than 10% accuracy. Fig. 2 shows  $^{10}\text{Be}$  activity in the Apollo 15 long core along with previous measurements of  $^{10}\text{Be}$  by  $\beta$  counting in 12002 [9], 14310 and 14321 [10]. All rock data are normalized to Apollo 15 chemical composition. In Fig. 2, a solid line shows the Reedy-Arnold calculation curve [3] normalized to the surface rock results. The absolute calculated value is a factor 2.5 lower than this line assuming the cross section ratio  $\sigma(^{10}\text{Be})/\sigma(^7\text{Be}) = 0.15$ . This large discrepancy is not yet understood. The Reedy-Arnold calculated  $^{53}\text{Mn}$  is 40% lower and calculated  $^{26}\text{Al}$  13% higher than measured values. Even though our new results are about 20% higher than this normalized line, the shape of the profile is in fairly good agreement with the Reedy-Arnold profile. The

measured half attenuation length,  $d_{1/2} = 120 \text{ g/cm}^2$ , is slightly longer than the Reedy-Arnold model ( $d_{1/2} = 107 \text{ g/cm}^2$ ). The main target element for  $^{10}\text{Be}$  in extraterrestrial material is O. Although  $^{10}\text{Be}$  is considered a high energy product, if we compare the mass difference from target nuclide,  $\Delta A$ , and half attenuation length of  $^{10}\text{Be}$  and  $^{53}\text{Mn}$  ( $d_{1/2} = 145 \text{ g/cm}^2$ ), it seems that  $^{10}\text{Be}$  is a medium energy product in contrast to high energy products such as  $^{36}\text{Cl}$  and  $^{40}\text{K}$  from Fe. We will need to complete the  $^{10}\text{Be}$  profile in the drill core and accurate cross section data for further study.

We wish to thank C. Kohl for her contribution to part of this work.
