THE STABILITY OF OXYAMPHIBOLES: EXISTENCE OF FERRIC-BEARING MINERALS UNDER THE REDUCING CONDITIONS ON THE SURFACE OF VENUS
D'Arcy W. Straub and Roger G. Burns, Dept of Earth, Atmospheric and Planetary Sciences, Massachusetts Institute of Technology, Cambridge, MA 02139.

Introduction: An enigma of Venusian mineralogy is the suggestion that Fe\textsuperscript{3+}-bearing minerals exist under the reducing conditions of the Venusian atmosphere. Analysis of the spectrophotometric data from the Venera 13 and 14 missions, combined with the laboratory reflectance spectral measurements of oxidized basalts at elevated temperatures, led to the suggestion that metastable hematite might exist on Venus [1]. Heating experiments, at 475°C when f\textsubscript{o}\textsubscript{2}=10\textsuperscript{-24}, demonstrated that the hematite to magnetite conversion is rapid, indicating metastable hematite is not present on Venus [2]. In addition to hematite, several other ferric oxide and silicate minerals have been proposed to occur on Venus, including laihunite or ferrifayalite [3], Fe\textsuperscript{3+}-bearing tephroite, oxyamphiboles [4], and oxybiotites [4]. Heating experiments performed on these Fe\textsuperscript{3+}-bearing minerals under temperature-f\textsubscript{o}\textsubscript{2} conditions existing on Venus suggest that only oxyamphiboles and oxybiotites may be stable on the surface of Venus.

Experimental Procedure: To simulate the appropriate redox conditions of the Venusian atmosphere, a Ni/NiO solid buffer was used. The Ni/NiO buffer, when heated to 475°C in an evacuated quartz cell, provides an f\textsubscript{o}\textsubscript{2} of approximately 10\textsuperscript{-24} [5]. The Ni/NiO buffer and mineral samples were wrapped in separate silver foil sheets. After heating periods of 1-30 days, the samples were quenched and analyzed by Mössbauer spectroscopy.

Results: The laihunite (25% Fe\textsuperscript{3+}) and the tephroite (16% Fe\textsuperscript{3+}) samples were each shown to have all of their Fe\textsuperscript{3+} reduced to Fe\textsuperscript{2+} when heated with the Ni/NiO buffer at 475°C for 7 days and 14 days, respectively. Conversion of the Fe\textsuperscript{3+} in these olivines to Fe\textsuperscript{2+} is demonstrated by the Mössbauer spectra of laihunite, illustrated in figure 1.

Heating experiments performed with a variety of amphiboles, including glaucophane, actinolite, hornblende, and kaersutite, indicated that Fe\textsuperscript{3+} ions initially present in the amphiboles are stable under Venusian surface conditions, where T-475°C and f\textsubscript{o}\textsubscript{2}<10\textsuperscript{-24}. For example, the Mössbauer spectra illustrated in figure 2 of hornblende before and after heating for 28 days show that virtually none of the Fe\textsuperscript{3+} has been reduced (cf. laihunite in figure 1). In a related experiment, hornblende was first heated in air for 20 minutes at 700°C to oxidize most of the Fe\textsuperscript{3+} ions, after which the oxidized sample was heated at 475°C with the Ni/NiO buffer for 7 days. The Mössbauer spectra of these reaction products, illustrated in figure 3, show that Fe\textsuperscript{3+} ions remain in the oxidized hornblende when heated under the reducing conditions of the Ni/NiO buffer.

Discussion: The stability of Fe$^{3+}$ in the oxyamphiboles may be explained by the intracrystalline redox reaction

$$\text{Fe}^{2+} + \text{OH} \rightarrow \text{Fe}^{3+} + \text{O}^{2-} + \frac{1}{2}\text{H}_2.$$ 

The Fe$^{2+}$ and O$^{2-}$ ions remain in the crystal structure as a result of this dehydrogenation reaction. Thus, no oxygen is added to the amphibole. This contrasts with the laihunite and hematite in which reduction, when heated with the Ni/NiO buffer, proceeds by diffusion of oxygen atoms from their crystal structures. The amphiboles lack this "excess" oxygen and cannot be reduced with the Ni/NiO buffer. Preliminary studies show that oxybiotites, which also can be formed by the removal of hydrogen during intracrystalline redox reactions, are also stable when heated at 475°C with the Ni/NiO buffer. These results also conform with phase equilibrium diagrams for iron-bearing calcic amphiboles and oxybiotites [6], which indicate that they have stability fields within ranges of temperatures, oxygen fugacities and atmospheric pressures existing on the Venusian surface.
