Introduction: Asymmetric and distorted absorption features in the near-infrared indicate the presence of hydrated materials on the surface of Europa [1]. A number of species have been proposed as the material which plays host to the waters of hydration. The most promising class of these may well be the ones which retain high numbers of water molecules. Earlier work [2,3] has shown discrepancies between near-infrared spectra of disrupted terrains on Europa gathered by the Galileo NIMS instrument and the spectral behavior of hydrated salts of low hydration states. Other work [4,5,6,7] indicates that these discrepancies are reduced at higher levels of hydration. Here we report additional laboratory measurements which strengthen the case for highly hydrated materials on Europa.

Europa Compared to Water Ice: Figure 1 depicts the spectrum of dark plains units on the trailing hemisphere of Europa compared to cryogenic spectra of hydrates and brines. The primary water absorption features near 1.0, 1.25, 1.5 and 2.0 microns (µm) are shifted and distorted in the Europa spectrum. These are composed of several smaller absorptions which combine to produce the broader features. Narrower absorptions such as the crystalline water ice absorption feature at 1.65 µm can be discerned in the Europa spectrum, particularly between 1.5 and 2.0 µm.

Absorption features of hydrated salts: Note also the well-rounded shoulders at the right of the 1.0- and 1.25-µm features in the Europa spectrum of Figure 1. These are affected by minor absorptions in the hydrated salt spectra, notably the epsomite spectrum directly above the Europa spectrum. Minor absorptions become more pronounced in the hydrates because the host molecule obstructs the interactions between independent H₂O molecules which cause molecular vibrations to occur over a broader frequency range. At low temperatures such as those found on the icy satellites, further reduction in interaction between energy states results in enhanced separation of these spectral features. This effect is subdued in molecules of higher hydration state because the increased number of water molecules are able to interact more freely.

Effect of Increasing Hydration: Epsomite (MgSO₄•7H₂O) displays the asymmetric absorption features endemic to the hydrates. However, it does not have the same shape as the Europa spectrum and contains a number of additional features not seen on Europa. Sodium sulfide nonahydrate (Na₂S•9H₂O) has broader absorption at 2.0 µm due to the greater number of water molecules, but the orientation of the hydrated waters about the sulfide gives rise to several absorptions at very different energies than seen in the sulfate hydrates; note the center positions of the 1.5- and 2.0-µm absorptions as compared to the sulfate hydrates. Mirabilite (Na₂SO₄•10H₂O) begins to more closely approximate the Europa feature shapes, but again exhibits additional features, notably at 1.75 and 2.2 µm.

Magnesium Sulfate Dodecahydrate: We have successfully synthesized magnesium sulfate dodecahydrate (MgSO₄•12H₂O) using a compressed-helium cryostat with programmable temperature controller at NASA-Ames Research Center. We began with a stoichiometrically appropriate mixture of MgSO₄•7H₂O and H₂O, which was placed in the environment chamber under dry nitrogen atmosphere. The temperature was programmed to oscillate about the eutectic and peritectic with a gradually decreasing amplitude over 16 hours. Each cycle resulted in solution of a higher proportion of H₂O, until the entire mixture had become dodecahydrite. The identity has been verified using differential scanning calorimetry. Because the dodecahydrate decomposes at temperatures above 267 K, the sample was maintained at subfreezing temperatures using a liquid nitrogen bath during transfer the calorimeter. Temperature-dependent spectra of the dodecahydrate are shown in Figure 2. The absorption features at 1.5 and 2.0 µm display the same asymmetry as the Europa features, with fewer additional absorptions as seen in the lower hydration state samples. However, as with the other hydrates, a cation-OH stretch at 1.35 µm [8] is apparent cutting into the shoulder of the transition between the 1.25- and 1.5-µm bands, in contrast to the well-rounded shoulders seen in the Europa and water ice spectra. At temperatures relevant to Europa (100K), fine structure in the dodecahydrate spectrum becomes apparent.

MgSO₄ and Na₂CO₃ Brines: When sufficient water is present to create a brine, many of these small spectral features become subdued [7]. This is partly due to the interactions with the numerous water molecules,
and partly due to scattering between salt and water grains within the frozen brine mixture [2]. However, the additional water also broadens the 2.0 micron feature, while failing to completely negate the 1.35-micron cation-OH stretch. Flash-freezing of brines or other solutions limits crystal growth times, creating many small crystals which act as scattering centers. Scattering centers decrease spectral contrast, reducing the influence of individual spectral features [2,9].

Mixtures: While no single material has yet provided a satisfactory match to the Europa spectrum, none have been conclusively ruled out on the basis of spectral arguments, either, and may be present in low abundances. Neglecting stability considerations, many of these materials could be present at 5 to 30 percent levels by weight. A mixture of several materials with coincident features at 1.5 and 2.0 microns could produce a spectral match without any one material contributing a strong enough discrepancy to contradict the NIMS data. While this has been tried with limited success using materials of low hydration state [1,2,3] new spectral measurements of highly hydrated materials [4,5] offer the potential to significantly improve upon these earlier studies.

Conclusions: As the number of waters of hydration increases, the near-infrared spectra of hydrated salt compounds begin to more closely approximate the Galileo NIMS results. Magnesium sulfate dodecahydrate exhibits uncanny yet imperfect similarities to the NIMS observations. Discrepancies remaining in the fine structure of brine and hydrate spectra (such as at 1.34 µm) could be exploited by a properly designed instrument to determine not only the materials, but also the relative proportions of materials, that make up the surface layer. Further laboratory measurements of as-yet unexamined compounds in the hydrate family may reveal even better correspondences.

Figure 1. Galileo NIMS spectrum of dark terrain on Europa (bottom) with cryogenic laboratory spectra of hydrated salts and brines. All laboratory spectra were measured at 100K.

Figure 2. Laboratory spectra of magnesium sulfate dodecahydrate. At warm temperatures the water of hydration absorption features are smooth; fine structure is most pronounced at cold temperatures.
