Triton

Io

Enceladus

Titan

Europa
Executive Summary

The purpose of this document is to frame the science objectives for exploration of the outer solar system. It is consistent with the 2013 Decadal Survey “Visions and Voyages” but will be kept up-to-date as new discoveries are made, models evolve, our understanding of solar system processes changes, and new questions are posed. This document will be used as a resource for defining technology development directions and needed laboratory experiments. This document may be used as a resource for mission and instrument science objectives.

Ultimately this document will guide our preparation for the outer solar system portion of the next decadal survey. The most important science objectives for each destination are identified, with the understanding that the over-arching theme will define the key questions to be addressed from the collection of intriguing topics. The over-arching theme will guide the prioritization that will be required, to recommend the next Decadal mission set.

What does the outer solar system provide, that uniquely addresses NASA’s top-level strategic goal to ascertain the content, origin, and evolution of the solar system and potential for life (2011 NASA Strategic Plan). How did the outer planets mold the solar system and create habitable worlds? The emerging science theme for future exploration of the outer solar system is to understand ice giants and ocean worlds. Our overarching goal can be summarized simply as “Explore Ocean Worlds, Small and Large”.

As stated in OPAG’s 2006 Scientific Goals and Pathways for Exploration of the Outer Solar System document, the unmatched diversity of bodies in the outer solar system provides the opportunity for a wide variety of scientific investigations. The giant planets provide insight into solar system formation through studies of their atmospheric composition and internal structure. The satellites of the giant planets – some comparable in size to terrestrial planets – offer the opportunity to study extreme environments on worlds that have experienced very different geologic histories. The rings and magnetospheres of the giant planets illustrate currently-active processes (of collisions and momentum transfer) that played important roles in early stages of solar system formation.

The outer planets feature prominently in molding the solar system in a complex endgame that appears to involve (a) migration of the outer two giant planets, Uranus and Neptune, from somewhere closer to the Sun to their present locations; and (b) giant planets scattering planetesimals into the inner solar system, delivering water and other life-critical materials to the terrestrial planets.

One of the primary opportunities in the outer solar system is the chance to explore oceans. The outer solar system is replete with ocean worlds including Europa, Ganymede, Callisto, Enceladus, Titan and Triton. Uranus and Neptune are ocean giant worlds, akin to water worlds found in extrasolar systems. In the inner Solar System only Earth has an ocean, and oceans are key to understanding the origin(s) and evolution of life.
Introduction: Explore Ocean Worlds, Small and Large

This section is now under construction

Liquid water is profoundly important to the existence of life on planet Earth. Water is found in abundance in the outer solar system, from the ice giant water worlds of Uranus and Neptune to the moons of all the gas giants. One of the most surprising revelations of the last decade is the number of moons that are likely to have internal liquid bodies of water – global “oceans” under their icy crusts.

Looking at the potpourri of science the outer solar system has to offer it is clear that we need to prioritize our exploration. We believe that understanding oceans should be the focus of future spacecraft expeditions.

This is a rich topic, touching on many important investigations already underway. The study of interiors leads to questions such as which moons have differentiated? Which icy moons, have liquid layers? Does tidal energy maintain those liquid layers? These questions lead to more questions about physical oceanography – how deep is the ocean? What is the composition? What is the pH? the salinity? Are there hydrothermal vents, hot spots, currents? What is the nature of the contact to the inner rocky core? What is the nature of the contact with the icy lid?

Surface-atmosphere interactions can occur in many ways, including rainfall, surface transport, and evaporation on thick-atmosphered bodies like Titan, condensation and sublimation on thin-atmosphered bodies like Io and Pluto, and jet-like and volcanic ejection of materials as on Triton, Io and Enceladus. Atmospheric production of materials through UV photolysis and other processes can also affect the abundance of organics, which eventually reach the surface and perhaps interior, as on Titan and perhaps Pluto and other places. Such interactions are complex and unique on a variety of outer solar system bodies and bear detailed study to fully understand.

Volcanism, the release of material from the interiors of bodies to their surfaces and atmospheres, occurs with unknown frequency and distribution across the solar system. It is of paramount importance to be able to recognize cryovolcanic processes because they reveal past or present endogenic activity and allow us to observe, and perhaps reach exposures of liquid water and any accompanying material. Such processes can substantially modify the geology of icy bodies, by erasing impact craters and reducing the surface age, smoothing out or burying older terrains, and bringing volatiles from the interior to the surface as seen on Io, Enceladus, and possibly Titan, Ariel, Ganymede, Triton and Pluto. Cryovolcanism also provides a link between interiors and atmospheres, controlling how and how often volatiles are supplied to the atmosphere.

Some of the most important considerations for ocean world habitability are to investigate environments that could provide geochemical disequilibria for extant life, and to understand the past environments of these worlds to determine if the geochemical conditions were ever sufficient to drive an emergence of life. The metabolic strategies that would be utilized in a particular environment would depend on the available geochemical free energy, i.e. the available electron donors and acceptors. Oxidants can be produced by processes such as radiative processing of ice, yielding e.g. O₂, H₂O₂, SO₄²⁻, CO₂; any of these can be used as an electron
acceptor for life if it is convected into the ocean at a high enough rate to be in close proximity to electron donors.

In ocean worlds where there is a water-rock interface, electron donors (fuels) could be provided to the oceans by serpentinization reactions, in which water interacts exothermically with Fe-Mg-silicate crust, resulting in high-pH (pH ~ 10–12) vent fluids rich in H₂, CH₄, and a variety of hydrocarbons. Serpentinization and the production of alkaline vents has been theorized for Europa and Enceladus; whether the other common types of hydrothermal vents on Earth, which are mostly produced by plate tectonics, could exist on ocean worlds is unknown. Also important for understanding habitability would be the composition of the oceans – for example the available species of phosphorus, nitrogen, iron and trace metals – and the properties of the rocky seafloor.

What types of minerals would we expect to precipitate on the seafloor of an ocean world and how would they affect the local environment? Carbonate precipitation, for example, is highly dependent on depth/pressure, CO₂ concentration in the ocean, and temperature. Hydrothermal precipitates are significant as well: for example, many vents on Earth build “chimney” structures of metal sulfides, which are electrically conductive and can provide an electron source for life at the seafloor, even abiotically driving redox reactions with surrounding ocean oxidants. Vents, depending on the type, can also precipitate sediments including sulfides/sulfates, clays, iron oxides/hydroxides – and some of these minerals can help catalyze redox reactions and concentrate biologically significant materials. For example, iron hydroxide precipitates (thought to have been common in ocean sediments and hydrothermal precipitates on the early Earth) can sequester and concentrate phosphates and organic molecules, can exert a major control on nutrient cycling by efficiently scavenging trace metals e.g. Ni²⁺ and can drive nitrogen redox chemistry. The concentration of oxidants in the ocean, the delivery of oxidants to the seafloor, and the sedimentation rate, are also significant: life in Earth’s seafloor sediments can respire (albeit at low rates) hundreds of meters below the surface due to penetration of O₂. How deep might oxidants penetrate into seafloor sediments on ocean worlds, and how deep might we have to go to find gradients / life today?

The evolution of ocean worlds over their history is also relevant, in order to determine if they ever had the conditions necessary to facilitate the emergence of life in the first place (since, it is possible for a world on which life never emerged, to still be considered “habitable” today). The alkaline hydrothermal origin-of-life model, which describes a prebiotic scenario applicable to the icy moons, posits that serpentinization reactions led to geochemical pH / redox gradients, and these combined with particular iron/nickel minerals that could act as nano-engines, drove metabolism into being from initial electron donors of H₂ and CH₄, and electron acceptors of CO₂ and NO₃⁻. So, what was the extent of water/rock interaction on ocean worlds: continual throughout their history; episodic; sufficient to maintain pH and redox disequilibria for geological time periods? Did these worlds contain the ingredients necessary for life as we know it – not just CHNOPS but also Mo, Fe, Ni, and the other metals that were likely an integral part of the first electron transfer metabolism? What was the pH of the ocean; was it acidic enough to produce a gradient against an alkaline hydrothermal fluid; and how has that changed over time?

The giant planets (hydrogen-rich Jupiter and Saturn, and water-rich Uranus and Neptune) are responsible for the formation, evolution, and continued existence of their moons’ water-based
oceans. Other aspects of these host systems (rings, rocky satellites, and the magnetospheres) help shape the environment of these oceans and play other critical roles such as tidal heating.

Current satellite formation mechanisms dictate that the materials found in ocean worlds—including the water ice “bedrock” materials—are closely associated with the composition of the host world. Understanding the bulk composition of giant planets is thus key to understanding the composition of their satellites. The predominance of trace materials such as hydrocarbons, nitriles, and other materials can, working with liquid water, form key astrobiological precursor material.

Under the warming, tidal influences of their parent planets, ocean-filled moons evolved to their current (possibly habitable) state. For example, Europa’s deep ocean is maintained largely by tidal heating driven by Jupiter and amplified by the orbit of Io. The interior structure of the host giant planet, which influences how well it gravitationally couples to its satellites, as well as the sometimes subtle gravitational interplays among all components of the system, are therefore relevant to understanding the energy balance of ocean-bearing satellites.

More speculatively, high energy particles impacting satellites may also be a factor in the energy available to drive ocean chemistry. Modulated by particles released by satellites including Io and Enceladus, charged by the host giant planet's magnetosphere, these charged particles plus cosmic rays can create disequilibrium species on an ocean world's surface which, if coming into contact with the ocean, open new pathways for pre-biotic (and biotic) chemistry.

While liquid water in satellites is most interesting because of its potential as a habitable environment, it is worth noting that liquid water plays a significant role in the circulation and weather of the giant planets. Just as on Earth, the condensation of water in uprising convective storm plumes serves to release energy sufficient to create violent winds and turbulence. On Saturn, water condensation is even thought to control the periodic "great storms" which are seen to alter the look and composition of the upper atmosphere every ~25 years.

To understand the satellite ocean worlds of the outer solar system, we must understand the giant-planet systems in which they reside. It should also be remembered that Uranus and Neptune, typically referred to as ice giant planets, are actually the largest ocean worlds in our solar system. Over half of the mass of these planets (about 10 times Earth's mass) is thought to be liquid water, with a large silicate core at the center, and a relatively small atmosphere above it.

Ultimately, our astrobiological goal in the outer solar system must answer more than "is life present". We should instead answer the more impactful question "why does life exist where it does, and why not elsewhere?". Our exploration strategy to answer this question should be systematic, with each mission furthering our understanding. Recall the 1976 Viking landers' life-detection experiments: given the lack of understanding of Mars' environment and surface chemistry, we did not, at that time, understand where, when, or how to meaningfully look for life on Mars. In recognition of the prematurity of the Viking experiments, understanding Mars' astrobiological potential has since been a 25-year quest with each mission building on the results of its predecessors. This long-term outlook affords a considered, step-by-step strategy that drives continuous forward progress toward definitive answers to astrobiological questions. Similarly, for outer solar system exploration we should eschew Viking-like "Hail Mary"
missions in favor of a progressive strategy wherein a series of missions each act individually to both (1) further the quest to scientifically constrain life's distribution and (2) perform preparatory explorations to enable follow-on missions. Such missions must necessarily seek to understand the chemical, physical, and geological processes and systems that affect both life and any measurements that seek to detect it.

Science objectives directly applicable to our theme of Explore Ocean Worlds are in blue text.

High-level themes for exploration of the solar system are summarized in Vision and Voyages (V&V), Table 3.1, and re-iterated in the appendix. Questions to be addressed at each body reference the V&V objectives where applicable.
GIANT PLANETS IN OUR SOLAR SYSTEM

The giant planets have played a critical role in shaping our Solar System. Current theory suggests their formation and migration had profound influences on the location and composition of the terrestrial planets, asteroids, and comets. The giant planets also hold clues to conditions in the proto-planetary nebula and the planetary formation process. These clues lie not only in their composition and internal structure, but also in the physical processes that occur within their unique environments. Looking beyond our solar system, we have found that giant planets are ubiquitous in exoplanetary systems. By coupling the "ground truth" of the giants in our system with what we see around other stars, the coming years will revolutionize our understanding of the evolution of planetary systems.

Giant planets seem to come in two distinct flavors. Jupiter and Saturn are gas giants, with over 90% of their mass made up of hydrogen and helium. Uranus and Neptune are ice giants, with about 65% of their mass thought to be water, 25% rock, and only 10% H$_2$ and He gas. The highest-level goals and objectives are the same for studying both types of giant planets, but we differentiate between gas and ice giants when discussing most details. (Regarding detailed science goals, it is worth noting that there have been two international conferences since the release of Visions and Voyages on the science to be done at the ice giants. Their conclusions are consistent with V&V, and have been used as an input into this document.)
We identify three driving goals in the study of giant planets and their magnetospheres:

**Goal 1: Explore giant planet processes and properties**

Explore the processes and properties that influence giant planets in our solar system (including origin/formation/evolution, orbital evolution, composition, atmospheric structure, and chemical, dynamical and other environmental processes).

**Goal 2: Use giant planets to further our understanding of other planets and extrasolar planetary systems**

Investigate observable processes and activities ongoing in our giant planet systems as an aid to understanding similar processes and activities on Earth, other planets and in other planetary systems.

**Goal 3: Determine giant planets’ influences on habitability**

Test the hypothesis that the existence and location of the giant planets in our solar system has contributed directly to the evolution of terrestrial planets in the habitable zone. (The possibility of habitable environments being created within giant planet satellites is discussed in the "Giant Planets' Moons" section of this document.)
JUPITER AND SATURN

1. What is the interior structure and bulk composition of the gas giants (including noble gas abundances and the isotopic ratios of H, C, N, and O)? [Q1, Q2, Q3]

Knowledge of giant planets’ bulk composition and interior structure (e.g. degree of internal differentiation) are key for understanding their formation and evolution. The properties of the deep interior are also a crucial boundary condition for the heat flow, composition, and dynamical processes acting in the observable atmosphere.

The interior structures of both Jupiter and Saturn are unknown in many key respects: the presence and size of a discrete rocky core; the extent and properties of metallic hydrogen; and whether or not there is evidence of core erosion. And while the Galileo probe has answered some of our compositional questions at Jupiter, key gaps remain. The ratios of noble gases in Jupiter point to an extremely low formation temperature for icy planetesimals (consistent with what is measured in most comets), while the $^{14}$N/$^{15}$N ratio measured is consistent with N$_2$ (and not NH$_3$) being the source species for most of Jupiter's atmospheric nitrogen. Several planetary formation models can explain these measurements, but make differing predictions for Saturn. Therefore, it remains of great interest to measure the noble gas and isotopic ratios on Saturn. Another important species to measure is water, whose abundance remains unknown on both planets (though the Juno mission---arriving in 2016---is designed to determine it at Jupiter).

2. What are the sources of internal heat, the nature of heat flow, and the radiation balance in gas giants? [Q7, Q9, Q10]

Planets form hot, and generally cool over time. Radiation to space is the ultimate heat loss mechanism, modulated by the ability of the interior and atmosphere to transport heat out to the radiative zone, and by secondary internal heating processes (e.g. radiogenic, helium rain). Is Helium rain-out a significant energy source on Saturn today?

All these energy-related processes are fundamentally important to the evolution and current structure of giant planets, influencing the temperature profile, the chemistry, and the dynamics throughout the planet. In particular, do these processes influence the unexpectedly high temperatures observed in the upper atmospheres of the solar system's gas giant planets, and the unexpectedly large radii of many giant planets seen around other stars? Another question common to all the giant planets is whether or not non-adiabatic temperature profiles exist in their deep atmospheres.
3. What is the global circulation and what are the dominant dynamical processes in gas giant atmospheres? What seasonal/temporal changes occur and why? [Q7, Q9, Q10]

The gas giants in our solar system have strong zonal winds, long-lived atmospheric features (e.g. Jupiter's Great Red Spot, Saturn's Polar Hexagon), as well as short-lived weather features (storms). It is not known, however, the depth to which these observed cloud-top features extend. The abundance and distribution of certain species (e.g. hydrocarbons, NH$_3$, H$_2$S, and the H$_2$ ortho-para ratio) is indicative of meridional, longitudinal, and vertical circulation patterns. We have seen seasonal changes and longer term quasi-periodic variations on Jupiter and Saturn (Saturn's most recent "Great Storm" being a prime example of a quasi-periodic, planetary-scale outburst).

4. What is the composition of gas giant atmospheres, and what are the photo- and thermo-chemical processes acting within those atmospheres (including cloud processes)? [Q1, Q2, Q7, Q9, Q10]

Understanding the composition and chemistry of gas giant atmospheres is necessary for understanding the current state of these planets, and provides clues about formation and evolution. For example, non-equilibrium species seen in the upper troposphere, such as PH$_3$, are a sign of vigorous vertical transport and hold clues to the bulk composition of the interior. Spatial and temporal variations in condensable species are a tracer of atmospheric dynamics.

5. What was and is the role of gas giant planets in creating/mitigating impact events throughout the solar system? [Q1, Q2, Q3, Q4, Q8, Q10]

Jupiter may play the role of protector of the inner solar system, minimizing the number of large, disruptive impacts later in our solar system's history including today (the many impacts seen on Jupiter yield stark evidence of this ongoing activity). Conversely, as discussed below, migration of the ice giants early in our solar systems history may be responsible for the late heavy bombardment in the inner solar system. Both these mechanisms are important factors in understanding the composition of the terrestrial planets and the emergence and subsequent evolution of life. Strong enhancements in noble gas abundances for non-radiogenic components that are preferentially trapped in cold ices below 40K (e.g., neon and argon) would be a key indicator of planetary migration from the cold outer solar system.
URANUS AND NEPTUNE

1. What is the interior structure and bulk composition of the ice giant planets (including noble gas abundances and the isotopic ratios of H, C, N, and O)? [Q1, Q2, Q3]

As with gas giants, knowledge of the fundamental properties of ice giants is key for understanding their formation and evolution. In particular, the abundances of various ices, the noble gases, and certain isotopes are diagnostic of competing formation theories, and may also provide evidence of radial migration of planets and planetesimals in forming planetary systems. The properties of the deep interior are also a crucial boundary condition for heat flow, composition, and dynamical processes acting in the observable atmosphere. These aspects are surely different for the Uranus system (with essentially no detectable heat flow) and the Neptune system (with the largest internal heat flow relative to absorbed sunlight of any giant planet in our Solar System), as discussed in the next question.

Some of the key questions about the interior structures of Uranus and Neptune are: What is the size of their rocky cores? How differentiated are they and---as some data suggest---do they differ in degree of differentiation? Do vast ionic oceans occur within both planets? Regarding composition, noble gas abundances and isotopic ratios are unknown or at best poorly constrained on both ice giants. There is also the lingering question as to whether the strong depletion of NH3 in their atmospheres relative to solar abundances is a sign of unmodeled chemistry deep in the planets or a bulk depletion in nitrogen compounds. And where Uranus and Neptune are found to differ, can this be explained by the giant impact thought to have knocked Uranus on its side late in the formation process?

2. What are the sources of internal heat, the nature of heat flow, and the radiation balance in ice giants? [Q7, Q9, Q10]

Is the low amount of internal energy being released by Uranus (an order of magnitude lower than Neptune releases) a sign of Uranus having cooled much faster (helped, perhaps, by the giant impact assumed to have knocked it on its side), or is this a sign of heat being trapped in the interior by a lack of convective transport? Can, in fact, a non-zero release of internal energy at Uranus be confirmed (the existing Voyager data allows zero as well as small values)? To what extent does Uranus' low internal energy release (which increases the importance of sunlight as an atmospheric energy source) make it an analog for giant exoplanets extremely close to their host stars (so called "hot Jupiters" and "hot Neptunes")?
3. What is the global circulation and what are the dominant dynamical processes in giant planet atmospheres? What seasonal/temporal changes occur and why? [Q7, Q9, Q10]

Even less is known about the zonal winds and long-lived (?) storms in the ice giants (e.g. Uranus’ Berg, Neptune’s Great Dark Spots), and these planets’ short-lived weather features (storms). Temporal variations on Uranus and Neptune are clearly seen as well, though the long orbital periods of those planets make it more difficult to distinguish seasonal from stochastic processes. While there are many similarities between ice and gas giants, these planets also have clear dynamical differences both between and within each class (e.g. Uranus appears to be less convectively active than Neptune). How all these dynamical features form and evolve is not clear (though there are intriguing hints that water condensation is important for convective processes), nor do we understand how or even if they are coupled to the deep interior or the uppermost atmosphere.

Does Uranus‘ low internal heat release mean its atmospheric dynamics are dominated by solar inputs? Does that make it an analog for the tropospheric dynamics of "hot Jupiters" around other stars?

4. What is the composition of ice giant atmospheres, and what are the photo- and thermochemical processes acting within those atmospheres (including cloud processes)? [Q1, Q2, Q7, Q9, Q10]

The composition and chemistry of ice giant atmospheres provides clues about their formation, evolution, and current state. Spatial and temporal variations in condensable species are a tracer of atmospheric dynamics. A detailed understanding of chemical processes may allow us to recognize anomalies that could be: signs of migration of Uranus and Neptune; residue of the giant impactor thought to have struck Uranus late in its formation; or evidence for exogenic infall of materials in the outer solar system.

5. What was and is the role of ice giant planets in creating/mitigating impact events throughout the solar system? [Q1, Q2, Q3, Q4, Q8, Q10]

Migration of the ice giants early in our solar systems history may be responsible for the late heavy bombardment in the inner solar system, thought to have provided many of the volatiles (such as water) found on the terrestrial planets today. As discussed above, Jupiter may play the role of protector of the inner solar system, minimizing the number of large, disruptive impacts later in our solar system’s history including today. Both these mechanisms are important factors
in understanding the composition of the terrestrial planets and the emergence and subsequent evolution of life. Strong enhancements in noble gas abundances for non-radiogenic components that are preferentially trapped in cold ices below 40K (e.g., neon and argon) would be a key indicator of planetary migration from the cold outer solar system.
GIANT PLANET MAGNETOSPHERES

1. How are the internal magnetic fields of the giant planets generated? What can we learn about the interior composition and evolution of these bodies from the study of the planetary magnetic fields? \([Q3, Q7, Q10]\)

The giant planets all have powerful magnetic fields generated by the convective motions of an electrically conducting interior. The magnetic field thus opens a window on the planet’s interior and its evolution throughout time, providing clues that constrain the formation, thermal evolution, composition and state of the interior of each planet in the solar system. The dramatically disparate magnetic fields of the gas giant twins, Jupiter and Saturn, demonstrate how uniquely valuable the magnetic field is in diagnosing differences in state and thermal evolution of two otherwise very similar (in composition) bodies. The magnetic fields of the gas giants will be thoroughly mapped by Juno and Cassini in the coming years. Of Uranus and Neptune, we know only that they possess dynamos dramatically unlike those of the other planets, magnetic fields with poles near the equator and magnetic centers well removed from the origin. Understanding dynamo generation in these ice giants will bring us closer to an understanding of the dynamo process and the Earth’s magnetic field. Planetary dynamos cannot be studied in any laboratory but for the solar system, where the experiment has been repeated for us, within bodies of differing composition, heat flow, and dynamics.

2. What are the properties and processes in giant-planet magnetospheres? \([Q3, Q7, Q10]\)

The magnetospheres of the giant planets map out a very different environment than the one we’re accustomed to, and have studied well. The giant planets provide a test of our knowledge of the processes at play in a magnetosphere and its interaction with the solar wind and internal plasma environment. Their rapid rotation, and (at Saturn and Jupiter) the introduction of mass from effusive satellites, elevates the transfer of angular momentum via current flow across field lines to paramount importance. These magnetospheres are laboratories in plasma physics, but they are also the realm within which the planet atmosphere and ionosphere interact with the distant satellites, exchanging mass and angular momentum. Jupiter and Saturn have demonstrated a great many unanticipated magnetospheric phenomena, as these planets yielded to orbital missions; one can but wonder discoveries await in the magnetospheres of two planets (Uranus and Neptune) with such unconventional planetary magnetic fields.
GIANT PLANET RING SYSTEMS

Investigations of planetary rings can be closely linked to studies of circumstellar disks. Planetary rings are accessible analogs in which general disk processes such as accretion, gap formation, self-gravity wakes, spiral waves, and angular-momentum transfer with embedded masses can be studied in detail. The highest-priority recommendation on rings in the decadal survey was accomplished: to operate and extend the Cassini orbiter mission at Saturn. Progress has also come from Earth-based observational and theoretical work as recommended by the decadal survey and others.

Cassini is revealing a wealth of new information about Saturn’s rings. Yet Jupiter, Uranus, and Neptune all have unique ring systems and just recently, a ring system was discovered around the largest Centaur, Chariklo. To quote "Vision and Voyages": "Exploring the rings of Saturn, Uranus, and Neptune is of high scientific priority, not only to deepen understanding of these giant-planet systems but also to obtain new insights into exoplanet processes and their formation in circumstellar disks, albeit of enormously different scale."

- What can the significant differences among ring systems teach us about the differing origins, histories, or current states of these giant-planet systems?
- Can the highly structured forms of the Uranus and Neptune ring systems be maintained for billions of years, or are they “young”? Are their dark surfaces an extreme example of space weathering?
- What drives the orbital evolution of embedded moonlets; how do they interact with their disks?
- What drives mass accretion in a ring system?

1. What is currently causing ring structures to change or evolve?

Cassini has revealed that significant structural changes in Saturn’s D and F rings have occurred on decadal and shorter timescales. Ground-based monitoring has detected similarly fast changes in the rings of Neptune and possibly Uranus. The mechanisms behind these changes remain mysterious, and it is highly desirable to see these changing structures in greater detail and to monitor them for future change. The Saturn ring system is significantly different from the ring systems of Uranus and Neptune and these differences provide information on the different conditions around these planets in the past. Understanding changes and evolution in ring systems has implications for processes at work over the history of the solar system.
Small moons that orbit within or just beyond a ring or ring system (“ring-moons”) act as tracers of a system’s past and present dynamics, as well as generating a wide variety of structure within the rings. For example, tracking variations in the orbit of tiny Methone placed constraints on the mass of its larger neighbor Mimas, and the mutual perturbations of the closely-packed inner moons of Uranus tell us that the system looked much different just millions of years ago. Ring-moons also sculpt the rings, creating gaps or partial gaps, spiral density and bending waves, and wavy ring edges. Discovering and tracking such moons is an important goal. The direct detection of orbital migration also remains a major goal, either for moons interacting with the rings or for embedded “propeller” moons, reflecting processes in proto-planetary disks. The past and present conditions of the ring disk are related to the conditions for satellite formation and help us understand how ring and satellite systems evolve.

An incredible amount of detailed structure is visible in Saturn’s rings.

2. What is the composition of ring systems, and how does that composition vary with time and space?

Cassini data show that the composition and thermal properties of particles in Saturn’s rings, as well as the characteristics of regolith on larger ring particles, vary over different regions of the rings, for reasons that need to be better understood. The overall composition of Saturn’s rings, remarkably rich in water ice, is an important constraint for the origin of the Saturn system. Large planetary ring systems such as Saturn’s provide information on the meteoroid flux and the pollution rates for the system and interconnection with the moons, important for understanding the origin of Saturn’s ring system.

The chemical and physical properties of Uranian and Neptunian ring particles are almost completely unknown. It is highly desirable to characterize them for comparative study. Planetary ring systems interact with both the central planet and with the moons as well as collecting dust from infalling interplanetary material. Determining the composition and physical characteristics of ring particles will inform our understanding of the solar system in the past.

3. How old are the known ring systems, and how did they originate?
Why does a massive dense disk surround Saturn alone? Why does only Neptune have arcs in its dense rings? Why is Jupiter the only planet without dense rings of any kind? What can these differences teach us about differing origins, histories, or current states of these planetary systems?

Incomplete ring arcs are seen circling Neptune in this Voyager image

Cassini data have fueled significant progress on the ongoing questions about the age and origin of Saturn’s rings, but it is still unclear whether the rings are young (100 Myr) or old (4 Gyr), as no single model explains all the data without difficulty. It is now even more desirable to bring our knowledge of other planetary ring systems up to a level where meaningful comparative studies to Saturn’s rings can be undertaken.

Chariklo, the largest Centaur, was recently discovered to have two rings. It is the first object besides the giant outer planets detected to have rings. What other bodies might have ring systems and how do they originate and evolve?

4. **What can rings tell us about their planetary surroundings?**
As delicate dynamical systems covering vast areas, rings sometimes function as useful detectors of their surrounding environment. The structure of the planet’s gravity and magnetism, changes in the orbits of its moons, and the population of meteoroids in the outer solar system are all illuminated by phenomena observed in rings.

5. **What can rings tell us about exoplanets or about protoplanetary disks?**
Planetary rings are an accessible natural laboratory for disk processes. Observed inter-particle interactions and disk-mass interactions provide windows onto the origins and operations of exoplanet systems and of our own solar system in its early stages.
Rings could be observed around transiting exoplanets, possibly yielding constraints on the planet’s spin and interior structure.

[Q1, Q2, Q7, Q10]
THE STUDY OF GIANT PLANETS’ MOONS

The diversity of the moons in the outer solar system has much to teach us about physical processes that have played out as the solar system evolved. The most pristine satellites record conditions from the earliest time of solar system history. The divergence of others as different evolutionary paths led the moons to become such unique worlds over the last 4.5 BY is a fascinating challenge that we are only beginning to understand. The prospect that many moons may harbor subsurface pockets or oceans of liquid water raises the exciting possibility that many habitable niches exist in our solar system.

V&V Goal 1: Understand how the satellites of the outer solar system formed and evolved

V&V Goal 2: Elucidate the processes that control the present-day behavior of these bodies

V&V Goal 3: Explore the processes that may result in habitable environments

The satellite sections that follow are organized beginning with the most pristine and primitive bodies. The least evolved [e.g. Umbriel, albeit based on limited data] have heavily cratered surfaces, near or at saturation, and may have undergone differentiation to a limited extent, if at all. Some show volatile mobility [e.g. Callisto, Iapetus] with sputtered atmospheres and/or regional frost deposits. Some feature surface evolution due to tectonics [e.g. Tethys, Ariel, Miranda].

Discussed in individual sub-sections:

Ganymede has an evolved, differentiated interior and is the only satellite known to generate its own magnetic field, but exhibits a moderately old surface that has undergone extensive tectonic activity.

Triton has a highly evolved interior, a youthful surface, and an atmosphere in vapor pressure equilibrium with surface frost.

Io and Enceladus feature ongoing active eruptions (silicate and icy, respectively), re-surfacing, and tectonic activity due to tides.

Titan has a youthful surface with geology recognizably similar to Earth (river channels, lakes and seas, mountains, dunes, and few impact craters) and a methane cycle analogous to Earth’s water-driven meteorology and hydrology, with clouds, rainfall, lakes and seas.

Europa has a very youthful surface (possibly active) that has undergone significant tectonic activity. Its subsurface ocean may possess all the ingredients for life and is the current focus of our quest to understand habitable zones in subsurface oceans.

Pristine to Primitive Satellites’ Objectives
1. What are the compositions (surface and bulk) and interior structures of the satellites, and what do they tell us about satellite formation and evolution processes, and formation locations?

Compositions, especially of volatile materials, preserve information about formation conditions, subsequent modification (both endogenic and exogenic), and volatile loss and exchange in the different giant-planet systems. Comparisons of diversity of mid-sized satellites within the Saturnian and Uranian systems, and comparisons between the two systems, illustrate dramatically different possible evolutionary paths and driving factors behind them. Another important question is whether the Uranian satellites are the result of system formation processes similar to those at other giant planets or are related to other events. Understanding of the bulk composition of the Galilean satellites will better constrain their interior structures and evolution. Laboratory work will help with interpretation of observations. Understanding surface compositions and the processes that drive them are also a high priority, e.g., how solar energy affects surface processes and how volatile re-distribution is expressed. Contrasting bright-dark surfaces (at the global and local scale) on Iapetus are the direct result of insolation-driven volatile redistribution, which may also explain the evolution of Hyperion's unusual surface and may have operated at Callisto to erode the surface and form small-scale surface topography.

Hyperion

2. What processes drove satellite formation and evolution and allow interior oceans and long-lived endogenic activity on even small satellites?

2.1 The dynamics of satellite formation processes have produced diverse systems: four large satellites at Jupiter, one large and seven mid-sized (>200 km diameter) satellites at Saturn, no large and five mid-sized satellites at Uranus, and two mid-sized (originally regular) satellites at Neptune along with the larger, irregular satellite Triton, believed to have been gravitationally captured. Understanding the nature of these systems of satellites, as well as of the individual satellites themselves, provides key constraints on the processes involved in their formation.
2.2 The energy sources available to the satellites are critical to their histories. Some of the most active satellites (currently or in the recent geological past) are the smaller satellites, e.g., plumes venting from the south polar terrain of 504-km-diameter Enceladus and coronae exceeding 300-km in size on 472-km-diameter Miranda. While, in comparison, Iapetus (1470-km diameter) cooled so quickly that it preserves the shape of a body in hydrostatic equilibrium with a 16-hour rotation period (current rotation period is 79.3 days). Explaining the energy budgets of the tidally heated satellites and their evolution through time remains challenging. The coupled evolution of satellite systems, and tidal interactions in particular, are important long-term sources of energy that need to be better understood through exploration as well as modeling.

2.3 Among the mid-sized satellites, Enceladus exhibits strong evidence for a sub-surface ocean while Rhea, Titania, and Oberon also have potential to host interior oceans. Determining the presence and natures of sub-surface oceans, especially whether liquid water is in direct contact with rock interiors as is suspected at Enceladus and Europa, is crucial to understanding the evolution and potential habitability of these bodies and how materials are processed within them.

3 What processes have shaped, and are continuing to shape, the satellites, and what controls which of the wide variety of observed processes occur?

3.1 The surfaces of the mid-sized satellites exhibit diverse expressions of geologic processes, each reflecting its unique history. In many cases, similar conditions and processes have led to extremely different expressions in landforms, cf. extension localized in the form of the Ithaca Chasma system on Tethys and globally distributed in faulting at a variety of scales on Dione.
Ithaca Chasma, Tethys (left) and fractures on Dione (right)

Fractures on Dione at pixel scales: 230 m (left) and 23 m (right)
Comparably sized, vastly different: Mimas (left; 396-km diameter), Enceladus, (middle; 504-km diameter), Miranda (right; 472-km diameter). (Not to scale.)

Giant impact basins and equatorial ridge on Iapetus

3.2 Cryovolcanism has been particularly difficult to identify on most icy satellites, perhaps an indication that it occurs only rarely or in integral association with tectonism, but the challenge may also be because it is difficult to identify or interpret in the context of icy materials. The only definitive example of active cryovolcanism is Enceladus' plume, and possibly at Triton and Europa (discussed in other sections). Intriguingly, Ariel has features that are strongly suggestive of extrusive cryovolcanism in the form of viscous flows. [Q4, Q6, Q7, Q10]
3.3 Impact crater distributions and cratering statistics have implications for understanding solar-system evolution, projectile populations and temporal changes therein, and bombardment history throughout the solar system. Crater morphologies provide valuable probes of target subsurface structures and properties, e.g., lithospheric thickness, heat flow, and material properties through time. [Q3, Q4, Q6, Q7, Q8, Q10]

3.4 Irregular satellites... section to be added.
Ganymede Science Objectives

The Galilean satellite Ganymede shows a tremendous diversity of surface features. The factors influencing its origin and evolution are related to composition (volatile compounds), temperature, density, differentiation, volcanism, tectonics, and the rheological reactions of ice and salts to stress, tides, and space interactions that are still recorded in the present surface geology. The record of geological processes spans from possible cryo-volcanism, through tectonism, to impact cratering and landform degradation. Remarkably, Ganymede has its own magnetic field, influencing the surface exposure to Jupiter’s plasma environment.

1. Interior Structure. What is the nature and history of Ganymede’s interior structure? What is the nature of Ganymede’s subsurface liquid ocean? What is the origin and evolution of Ganymede’s dynamo magnetic field?

Gravity and magnetic field evidence point to a fully differentiated structure for Ganymede, in that its inferred moment-of-inertia is the lowest of any solid body in the solar system and it possesses its own intrinsic dipole magnetic field. Ganymede is thus inferred to be differentiated into a massive icy shell, rocky mantle, and iron core. The iron core must be at least partially molten to sustain a dynamo. Magnetic field evidence has been further interpreted to imply that Ganymede also possesses an induced field in the manner of Europa and Callisto, and thus possesses a conducting layer closer to its surface, presumed to be a layer of salty water sandwiched between a less dense ice I layer above and denser, higher pressure ices below.

Two critically important questions remain. The first is the very existence of the dipole field. The field requires convection of liquid iron (or liquid iron-sulfur, etc.), which implies a minimum power output from the core. All models to date, even those that invoke tidal heating episodes in the past, have failed to yield the power necessary at the present day. The second question is how the evolution of Ganymede’s interior directly or indirectly was responsible for the resurfacing of much of Ganymede, creating its bright terrains. Did Ganymede differentiate relatively late in its history? Was an internal melting and refreezing episode driven by passage through a tidal resonance? Or did something completely different occur? Furthermore, why did Callisto not follow this path?

Answers to these questions will rely on improved measurements of Ganymede’s gravity and magnetic field, including non-hydrostatic components of the former and time variability of the latter. Global topographic measurements as well as determination of the tidal response of the surface (Love numbers) will facilitate interpretation of the gravity field, determine the thickness of the upper ice shell, and constrain the depth of the (putative) internal ocean and possible layers of exotic salts. Seismic information would be definitive. The nature of Callisto’s and Titan’s interior are directly relevant to this objective.

[Q1, Q2, Q3, Q10]

2. Surface geology. What are the geologic processes responsible for Ganymede’s surface features? What are the ages of Ganymede’s terrains and landforms? Has cryovolcanism and or diapirism played a major role in renewing the surface? Has lithospheric spreading
occurred? What are the stress mechanisms that have shaped the surface tectonics? What is the role of volatile migration and landform degradation on its surface?

Ganymede’s mix of young and old terrain, ancient impact basins and fresh craters provides landscapes dominated by tectonics, icy volcanism, and the slow degradation by space weathering. Understanding this icy satellite’s surface processes can help us understand how icy worlds evolve differently from rocky terrestrial planets. Ganymede’s surface is subdivided into dark, densely cratered ancient plains (perhaps essentially primordial and somewhat similar to the surface of Callisto), covering about 1/3 of its total surface and bright, less densely cratered, heavily tectonized, grooved terrain. In addition to craters, dark terrain also displays hemisphere-scale sets of concentric troughs termed furrows, which are probably the remnants of vast multi-ring impact basins, now broken up by subsequent bright terrain tectonism. This type of terrain appears relatively dark due to the addition of a non-water ice contaminant that appears to be concentrated at the surface by a variety of processes including sublimation, sputtering and mass wasting.

Bright terrain separates the dark units in broad fault-bounded lanes up to several hundred kilometers wide, termed sulci, typically comprised of linear or curved parallel fault scarps forming closely spaced grooves. The bright terrain units formed predominantly at the expense of dark terrain through a poorly understood process of volcanic and tectonic resurfacing, causing the partial or total transformation of dark terrain into bright terrain by tectonism. (Generally, grooved terrain represents rifts created by extensional stress). Several caldera-like, scalloped depressions, termed paterae, found in the bright terrain represent probable volcanic vents, and ridged deposits in one of the largest paterae have been interpreted as cryovolcanic flows. The geologic process of resurfacing bright terrain is incompletely understood. Smooth units which embay other surface units such as crater rims, in some parts less densely cratered, are thought either to represent cryovolcanic flows, extruded as icy slushes or to be issued from mass wasting processes along slopes. The smoothest units also exhibit some degree of tectonism, implying that cryovolcanism and tectonic deformation are closely linked. Despite much effort to understand the patterns of Ganymede’s grooves (at global, regional, and local scales), we do not yet understand the stress mechanics that have shaped the surface, and the possible roles of (for example) non-synchronous rotation, true polar wander, and convection. Although the ultimate driving mechanism for groove formation is uncertain, there are many intriguing possibilities that it may be tied to the internal evolution of Ganymede and the history of orbital evolution of the Galilean satellite system.

Impact features on Ganymede exhibit a wider range of diversity than those on any other planetary surface. They include vast multi-ring structures, low-relief ancient impact scars called palimpsests, craters with central pits and domes, pedestal craters, dark floor craters, and craters with dark or bright rays. The subdued topography of Ganymede’s oldest impact craters imply a steep thermal gradient in Ganymede’s early history, with more recent impact structures reflecting a thicker and stiffer elastic lithosphere. Such an interpretation indicates a much warmer shallow subsurface early in Ganymede’s early history than at present.  \(Q10\)

3. What is the composition and origin of Ganymede’s surface materials and how do they
The chemical composition of the visually dark, non-water-ice material on Ganymede is presently unknown. Organics and hydrated salt are possibilities, but there may also be a component of hydrated sulfuric acid, as has been proposed for dark material on Europa. Given these uncertainties regarding its composition, the component of exogenic material in the Ganymede non-ice material is also unknown, as is whether the material is of a single uniform composition over Ganymede’s surface. Understanding how these non-ice materials correlate with the surface geology at a wide range of spatial scales, and whether they are linked to the subsurface at all, will aid in identifying their nature and origin(s). [Q10]

Large-scale, sublimation-driven landform modification is notably rarer in Ganymede’s dark terrain than on Callisto, which may indicate a relative paucity of highly-volatile CO$_2$ ice in Ganymede’s near-surface, which is thought to be the principle force behind sublimation weathering. In addition, Ganymede does not exhibit the same bright ice pinnacles at topographic peaks and crater rim crests as are commonly seen on Callisto, and which are thought to be redeposited water ice. Close scrutiny of Ganymede’s dark terrain is therefore key to understanding the role of volatile migration in shaping Ganymede’s surface as well as the relative inventories of certain volatiles within the crusts of Ganymede and Callisto.

The composition and physical state of materials on Ganymede’s surface will be altered by radiation weathering effects, but what compounds are produced through radiolytic processes on the surface of Ganymede, and their lifetimes and rates of formation, are not known. Determining the abundance and distribution of such compounds on the surface will help inform as to the intensity and type of magnetospheric bombardment over the surface of Ganymede. Defining the temporal cycle of the oxygen species on Ganymede is a specific objective.

4. What are the characteristics of the intrinsic magnetic field of Ganymede (strength, size, variability) and of Ganymede’s exosphere and ionosphere?

The properties of Ganymede’s magnetic field are not well constrained. These include the size of the magnetosphere, as manifested on the surface by the location of the boundary between open and closed field lines. This boundary may correlate to certain surface and exosphere features if interactions with such features are significant. A key objective of a magnetospheric investigation would be to determine the particle distributions of various species around Ganymede, including what neutral species are present in the exosphere beyond those that have been inferred already. Such an investigation will help characterize Ganymede’s exosphere, in particular by defining the morphology and dynamics of its asymmetry, and the extent to which Ganymede’s magnetic field generates such asymmetry. It would also aid in identifying the processes of production and loss of the exospheric particles and how such processes vary in space and time. Determining the distributions of charged particles will help in defining the extent, structure and dynamics of Ganymede’s ionosphere as well as the nature and controlling factors for the aurorae that have been observed at Ganymede’s poles. A final question is whether Ganymede’s magnetosphere is strong enough to prevent Ionian sulfur (which is thought to be present on Europa’s surface) from impacting Ganymede’s surface. [Q10]
Neptune’s moon Triton has only been studied by one spacecraft. Voyager flew by in southern summer and imaged just one side of Triton in high resolution. Triton’s youthful surface has unique geological features. Its nitrogen atmosphere is in vapor pressure equilibrium with surface frost. Remarkable plumes jet up to 8 km from the surface.

1. Interior Structure. What is the nature and history of Triton’s interior structure? Does Triton have a subsurface liquid ocean? Does Triton have a current or past dynamo magnetic field? What is the current heat flow?

If Triton was captured early in the history of the Solar System, then tidal evolution to a circular orbit and differentiation may have been completed within several $10^8$ yrs, followed by billions of years of impact cratering. Yet the surface is lightly cratered. New models of obliquity evolution suggest that modest tidal heating is ongoing. Can radiogenic and tidal heating today cause convection in a subsurface layer that erases craters and/or otherwise renews the surface? Is a metallic inner core dynamo possible?

Subsurface oceans may be a common feature of icy moons, and Triton’s young surface age (<100 Myr, possibly <10 Myr) may be indicative that it too has a subsurface ocean. If Triton possesses an internal ocean, is it ‘perched’ above high density ice (perhaps like Ganymede) or in contact with the rock core (like Europa)? If Triton collided with existing moons in orbit around Neptune during its capture, its composition could be a mix of planetocentric and helio-centric material. Is Triton still colliding with planetocentric debris?

[Q1, Q2, Q3, Q10]

2. Surface geology. What are the geologic processes responsible for Triton’s unique surface features? What is the global cratering record on Triton? Has cryovolcanism played a major role in renewing the enigmatic cantaloupe terrain? How spatially homogeneous is Triton’s surface, or, put differently, what undiscovered geologic features lie in regions that were not well-imaged by Voyager?

Triton’s surface age of <10 - 100 Myr is derived from the sparse number of craters on its surface. Triton’s young surface with relatively few craters stands out among moons in the solar system and puts it in a class with Io, Europa, Titan and Enceladus – other moons with active surface processes today.

What is the range of ages of Triton’s surface units? We need a global data set to fill in Voyager’s limited surface coverage and spatial resolution.

Many landforms on Triton are unique in our solar system (e.g., cantaloupe terrain) – how are they formed? What is the global distribution of geological terrains? What remains to be
discovered? And how does the interaction of tidal dissipation, heat transfer, tectonics, cryovolcanism/diapirism, and surface-atmosphere interactions drive resurfacing of Triton? [Q10]

3. **Surface composition and atmosphere.** What does Triton’s surface chemistry tell us about its origin? Is oceanic chemistry expressed on its surface? How are different composition ices partitioned across the surface? What is the nature of Triton’s global circulation and climatic response?

Changes in atmospheric pressure since the Voyager flyby have been detected in stellar occultations observed from Earth. Seasonal volatile migration is predicted, as Triton’s nitrogen atmosphere in vapor pressure equilibrium with surface ices responds to changes in insolation. How has seasonal volatile migration affected the south polar cap and atmosphere since Triton has gone from southern spring (Voyager) to summer? How much mass has been transferred into the atmosphere and northern polar region? The compositions of Triton’s individual surface units are unknown because Voyager did not have a way to determine surface composition, and ground-based observations have limited spatial resolution. Volatile ice migration is expected from climate models – which ices are where when? How does the seasonal sublimation and migration of volatiles into and out of the atmosphere drive winds?

How do volatile inventories compare between Triton and Pluto and other dwarf planets of the transneptunian region? [Q9]

4. **Triton’s plumes.** What is the source of Triton’s plumes? Are Triton’s plumes a result of solar-driven activity (like Mars)? Or are they endogenic (like Enceladus)? What do the sites and timings of occurrence tell us about the energetics, relevant processes, and the nitrogen reservoir?

What do the sites and timings of plume occurrence tell us about the energetics, relevant processes, and the nitrogen reservoir? Is there a true polar cap?

If solar-driven, similar activity may also be occurring on Mars, and Triton may prove to be a wellspring of information about this unearthly phenomenon.

If endogenic the plumes may be sampling a subsurface material and possibly a subsurface ocean. Similar arguments apply to recent cryovolcanism. These would be important for understanding Triton’s internal heat flow and tectonics, and would add Triton to the list of key astrobiological targets. [Q6]

5. **Triton’s interaction with Neptune’s magnetosphere.** How does highly conducting Triton ionosphere interact with the corotating magnetosphere of Neptune? How is Triton’s extremely strong ionosphere generated and maintained, and are magnetospheric interactions key? Does an induction signal tell of an interior ocean?

How is the relatively dense neutral torus of Triton formed, and what is its relationship to loss processes from Triton’s atmosphere? Voyager radio science observations revealed a significant ionosphere with a well-defined peak at ~350 km altitude; however, the distance and the geometry of the Triton closest approach precluded in situ observations of either the ionosphere or its interaction with Neptune’s magnetosphere. Neptune’s magnetic field has a large tilt, so (like in the Jupiter-Europa system) an induced magnetic field should exist if Triton contains a conductive subsurface ocean. [Q10]
Io Science Objectives

Jupiter’s innermost Galilean satellite, Io, is extremely active on the surface, in the interior, and in its atmosphere and exosphere. There are more active volcanoes than on any other body, including Earth (that is, currently active as on Io rather than dormant), and these volcanoes connect to the tidally worked interior and to the atmosphere and Jupiter environment. Understanding the processes that lead to the generation and consequences of volcanic eruptions will inform studies of Europa and the other Galilean satellites, Jupiter and the magnetosphere, and volcanism and tectonism throughout the solar system.

1. What are the processes that control Io’s volcanic eruptions and how do they vary spatially and temporally?

Over one hundred active volcanic centers have been identified, yet the generation of the volcanoes, the style and duration of eruptions and connectivity between volcanic centers are poorly understood. Furthermore, it is not known what their compositions are or if the eruption type at a single location changes with time. In addition, minor volcanic types that are sulfur or SO$_2$ dominated have been suggested, but their extent is unknown.
2. What processes form Io's mountains and what are the implications for tectonics under rapid resurfacing and high heat-flow conditions?

There are more than 100 mountains on Io, the majority appearing to be tectonic, rather than volcanic, structures. There is no obvious global pattern to their locations; with the exception of a bimodal distribution with longitude and while mountains have local associations with paterae, globally there is no correlation. The most favored model for mountain formation since the Galileo era invokes compressive stresses in the lithosphere induced by rapid volcanic resurfacing. The details of the mountain formation process and the relationship of this process to Io’s volcanism, and in particular the formation of paterae (volcano-tectonic depressions), have yet to be discovered. It is also unknown whether the nature of the process has changed with time. These studies can reveal more about Io’s crustal properties and evolution and transfer of internal heat and similar mountain-building processes on other planets. {Q3, Q7, Q10}

3. What are the magnitude, spatial distribution, temporal variability, and dissipation mechanisms of tidal heating within Io? How is heat transfer to the surface controlled by internal structure? What is the internal structure (temperature, composition, deformation), is there a magma ocean and what is its nature? How does the dramatic tidal heating of Io help us to understand tidal heating as a fundamental process operating now, or in the past, throughout the solar system and beyond?

Io’s extremely active volcanism is explained by excessive amounts of internal tidal heating. Measurements of Io’s heat flow from ground-based telescopes and Galileo PPR data are around
2 W/m², more than twice as large as the upper limit expected for steady-state tidal heating models, yet how this has affected Io’s interior and surface is still unknown. Comparisons of spatial variability in Io’s volcanoes to tidal heating models show that the distribution of hotspots is more consistent with the heating occurring in the asthenosphere rather than the mantle. Magnetometer data from Galileo suggest the presence of an interior magma ocean, yet how large or deep this ocean is and how it is maintained under a density inversion has not yet been determined. The temporal variability of heat flow and volcanic output are not well known, and studies can reveal how tidal heat is transferred to the surface. Tidal heating is the major contributor to active surface geology in the outer Solar System, so studies of hyperactive Io are essential to furthering our understanding of tidal heating in general. [Q2, Q6, Q7, Q10]

4. What is the temporal and spatial variability of the density and composition of Io’s atmosphere, how is the variability controlled, and how is the atmosphere affected by changes in volcanic activity? How does the surface chemistry react with the atmosphere?

Io’s atmosphere appears to be controlled by both volcanic emissions from Io’s near-surface and deep interior and sublimation of surface volatiles. However, which process is dominant is not yet known and has implications for the vertical and thermal structure of the atmosphere, its lifetime and composition. [Q2, Q6, Q7, Q10]

5. How does material and energy flow within and between the Io torus and Jupiter’s magnetosphere and how does that change with time? Is Io’s magnetospherically-driven volatile loss an archetype for similar volatile loss processes that may have been important elsewhere in the solar system and beyond? How does Io’s atmosphere affect the state of the Io torus, the Jovian magnetosphere, and aurorae?
As material escapes from Io’s low gravity, it forms a vast neutral cloud. The Io Torus, which extends around Jupiter in Io’s orbit, is a ring of plasma also created from Ioenic material. The coupling between these plasma populations is a fundamental and unresolved problem in space physics. The interactions between Io’s volcanoes, atmosphere, neutral cloud, and torus are complex and have implications for the entire Jovian system and beyond. [Q2, Q6, Q7, Q10]
Enceladus Science Objectives

Despite its size (500 km in diameter), diminutive Enceladus has emerged as one of the most compelling targets for planetary exploration. Powered through its gravitational resonance with neighboring Dione, Enceladus maintains vigorous activity at its south pole, including active tectonics, high heat flow, and most importantly, ongoing venting of plume gases and icy particles that betray a rich chemistry indicative of a subsurface sea.

1. *Enceladus’ Interior.* What is the nature of Enceladus’ interior? That is, what is the size and shape of its rocky core, the thickness of its icy crust as a function of location, and what is the thickness and extent of its subsurface ocean or sea? Gravity models are consistent with at least a regional sea at the south pole and a large, low density (~2500 kg/m³) core. But is the sea global? Whatever its extent, any subsurface sea or ocean should be more directly confirmed. Need to update now that global ocean is detected from libration data.

How uniform is the ice shell thickness? What are the various contributions from thickness and density (salinity, clathrates, porosity) variations?

If Enceladus’ core is low density, is it porous, and is there internal hydrological circulation?

All of these questions feed into something more fundamental regarding Enceladus’ origin. Is Enceladus an original regular satellite, as is usually assumed, or was it born from a massive mega-ring during a later epoch, as has been proposed by some workers? [Q1, Q2, Q10]

2. *Composition of Enceladus’ Ocean.* What is the composition of the ocean, sea, or liquid reservoir that apparently feeds the plumes erupting from the South Polar Terrain? How does this composition relate or map to in situ mass spectrometer and dust or other measurements of plume vapor and solid particles?

Are ammonia, methanol, chloride or bicarbonate salts, or some other materials, depressing the melting point and enabling a liquid water layer or changing rheological properties within Enceladus’ solid ice shell?

What are the global characteristics of the ocean, in terms of temperature, oxidation state, pH, and Eh? What does ocean chemistry imply for Enceladus’ origin and evolution? Are the organics inferred from Cassini plume data primordial or a product of synthesis within Enceladus, either currently or in the past? [Q1, Q3, Q4, Q10]

3. *Enceladus’ Plumes.* How do the mechanics of Enceladus’ erupting plumes actually work? What are the roles and importance of tidal and endogenic stresses (that is, those due to convection, diapirism, freezing and melting of the sea/ocean)?
How does the liquid water reservoir communicate with the surface?

What are the physical and chemical conditions in the plumes? What are the plume characteristics, particle masses, size, and velocity distributions? How long-lived are the plumes? Does plume production vary in time? Are plumes cyclic, episodic? Do source regions migrate along the tiger stripes?

Were other regions on Enceladus cryovolcanically active in the past (or even active today at a low level)? And how does plume fallout affect Enceladus’ surface? How do the plumes feed the E ring? What are the escape and resurfacing rates?

4. **Enceladus’ Tidal Energy.** Where is the tidal energy that powers Enceladus’ activity actually deposited? What is the balance between anelastic dissipation in the solid ice shell, frictional dissipation on faults in the icy lithosphere, and oceanic dissipation? Moreover, how has this varied in the geological past and across different terrains? Under what circumstances could there be or have been substantial tidal dissipation in the rocky core?

What is Enceladus’ heat flow and how is that heat flow distributed? How is that heat flow stored (if it is) and transported? A related question is how long can a liquid ocean exist on Enceladus?

How large are the tidal stresses, and how much tidal deformation occurs? What is the nature of the tectonic features on Enceladus? Why do tectonic expression and patterns vary across the surface? To what extent is the active tectonics on Enceladus a model for geologically recent tectonics on Europa and older tectonized terrains on Ganymede and other icy satellites?

5. **Enceladus’ Habitability.** Is Enceladus’ subsurface sea habitable? What do the answers to the above questions imply for conditions in the geological past to have been conducive to the origin and evolution of life.

We know there is ‘CHON’ (carbon, hydrogen, oxygen and nitrogen) on Enceladus, but is there ‘CHONPS,’ and are other elements bioavailable? What energy sources are potential available for life? And what lessons from Enceladus apply to Europa, and visa versa?

Finally, given the availability of water, at least some biogenic elements, and tidal energy, there is the simple question: is there extant life within Enceladus?
Titan Science Objectives

Titan, the largest satellite of Saturn, larger than the planet Mercury, shares more ongoing physical processes with Earth than any other planetary body. It possesses a nitrogen-based atmosphere more massive than our own with a unique, organic-dominated surface. Active rainfall and erosion create rivers, lakes, seas, eroded landscapes, and vast fields of sand dunes. The Titan environment is rich with complex organic molecules that inform studies of prebiotic chemical evolution, and its climate has many analog processes to those on Earth, such as air-sea exchange, moist convection, seasonal polar vortices, and greenhouse and antigreenhouse effects. Underlying all this is a Ganymede-sized icy satellite with a deep internal ocean of liquid water.

Goal 1: Explore surface, atmospheric, and interior processes

Explore the processes currently affecting the surface, atmosphere, and interior of Titan today and how these processes are related to Titan's history and composition, and relate them to similar processes on Earth and other solar and extrasolar planets.

Goal 2: Investigate change in the atmosphere and surface

Investigate how and where change occurs on Titan today as a result of orbital and internal variations, and how large-scale climatic and evolutionary changes have affected Titan over its geologic past, as a means to help us understand similar processes and activities on Earth and other planetary bodies.

Goal 3: Determine habitability

Investigate both of Titan's liquid reservoirs --- hydrocarbons on the surface in lakes and seas and water in a deep subsurface ocean --- and determine if they have been amenable to the rise of life, or its molecular precursors.
1. What processes are active on Titan’s surface and in the lithosphere and how have these processes, and the surface of Titan, changed over time?

Surface features that are the end result of extensive atmospheric interaction via erosion and internal energy such as rivers, lakes, mountain belt, dunes and potential cryovolcanoes have been observed on Titan. The evolutionary history of these features, and their current state and activity, is not clear, though the surface is relatively young as evidenced by the presence of only a handful of identified impact craters. The primary mode of resurfacing, whether by erosion, cryovolcanism or overturn, tectonism, or deposition from atmosphere-derived organics, or whether the primary mode has changed over time, is not yet determined. Obtaining methane and ethane fluids to enact the surface erosion requires an interplay between the surface, interior and atmosphere. Exchange of volatiles from the interior to the atmosphere may occur via disruption of clathrates, which contain methane, ethane and other noble gases in near-surface and interior ices, though how frequently and where this occurs is not known. [Q2, Q7, Q10]

2. How and when do changes in Titan’s atmosphere occur, and how are these expressed at the surface?

Seasonal changes are thought to occur in Titan's atmosphere, based on studies of orbital parameters, surface morphologies and upper atmospheric chemistry. Titan's orbit requires it to undergo shorter and more severe southern and longer and more subtle northern summers, which has likely led to the observed presence of vast lakes and seas in the northern hemisphere. Solar cycles have an effect on the methanological cycle in the upper atmosphere, which affects the overall atmospheric dynamics and deposition of materials on the surface. This also affects atmospheric flow and can be observed as changes in clouds and precipitation. Long-term changes likely cause rising/falling lake levels, modifications to dune fields and wind streaks, and regional climate change. The dynamics of Titan's atmosphere can be compared with those of Earth, Venus and Mars and mutually inform their evolution. [Q2, Q3, Q7, Q10]

3. What was the thermal evolutionary history of Titan, and how was/is thermal activity expressed at the surface?
Based on moment of inertia measurements, Titan appears to have a low degree of differentiation. Given its size and young surface, more internal differentiation might be expected. There could be more differentiation while maintaining the observed moment of inertia if the silicate mantle were in a state of hydration. Studies of the mode and amount of release of internal heat would inform the amount of internal differentiation as well as the amount of energy available for tectonism and volcanism. In addition, understanding the release of volatiles from the interior, such as ammonia and methane, is key to understanding differentiation and volcanism. Studies of tectonism and volcanism on Titan also helps us understand the communication between the liquid water ocean at 50 km depth below the ice lithosphere and the organic-rich surface, which has astrobiological implications. \[Q2, Q3, Q7, Q10\]

4. **What processes occur in Titan’s atmosphere and on the surface that lead to the formation of organic molecules, and could these materials undergo prebiotic and biotic processes?**

Photodissociation of methane high up in Titan's atmosphere leads to the formation of long-chain organic (C-H based) molecules. Cassini has detected an impressive variety of species including ethane, hydrogen cyanide, propane, butane and acetylene, and many other higher-mass hydrocarbon and nitrile compositions. However the details of the ion neutral chemistry, the effects of lower atmosphere radical chemistry, the effects of coagulation and condensation processes, and how abundant they are and the degree of the incorporation of nitrogen have yet to be determined. In addition, oxygen from Enceladus has the potential to form amino acids in Titan's atmosphere. These organic molecules in Titan's lakes, on the beaches, and in the rivers have the potential for prebiotic and biotic processes. Yet where these processes could occur, under what chemistries, and at what rates is not yet known. \[Q2, Q6, Q7, Q10\]

5. **How can Titan inform us about extrasolar planets?**

An extrasolar planet similar to Titan in size and effective temperature would orbit a typical M-dwarf star at around 1 AU --- far outside such stars' habitable zones where tidal locking, coronal mass ejections, flares, and inefficiency in volatile delivery during formation affect planetary evolution. Around the smallest M-dwarfs, this distance would shrink to 0.2 AU, but even were we to disregard these, the number of remaining M dwarfs vastly outnumbers G dwarfs like the Sun, leading to a high probability of finding Titan-like bodies in the galaxy. Because the 1 AU environment around M dwarfs is benign, in the same sense as is that of our Sun, planets at that distance from an M-dwarf should have stable methane hydrologic cycles for which our own Titan can be a good guide.
Europa Science Objectives

Europa is among the most promising candidates in the search for life beyond Earth due to its young surface, energetic environment and potentially rich inventory of ingredients for life that has likely existed over the lifetime of the solar system. Among the icy satellites of the outer solar system, Europa is also in a special position: having been visited by both Voyager and Galileo, hypotheses regarding Europa are vastly more mature than for other bodies. If the NASA mantra of “fly-by, orbit, rove, and return samples” is the path forward, Europa will certainly be included in the “lander” edge of this spectrum. Because of what we know already, there are many detailed investigations of merit for Europa. However, it is what we don’t yet know…and what we wish to…that inspires the following five fundamental topics that define Europa science for the coming decades.

1. How does Europa’s Ice Shell Work?

Europa’s surface is riddled with fascinating geology, and is scarce on craters. The surface, with an estimated average age of 40-90 Ma, must be recycled or reprocessed in order to explain its lack of craters. How does this happen? At present, while the preponderance of evidence suggests an ice shell thickness of at least 20 km, arguments for a thinner shell still have observational merit. These open issues inspire a range of questions that address just how Europa’s still-active ice shell operates.

The most prevalent of Europa’s surface features are its ubiquitous ridges. These are of several types, and the origin of these features is highly debated. Ridges are characterized as single, double, and ridge complexes, and these include both linear ridges, and cycloids, with arcuit cusps that suggest variations in stress over time. These fractures may penetrate just the brittle shell, or completely through the ice shell. These are also thought of as possible conduits for material from the deeper ice shell or ocean to reach Europa’s surface. It is generally thought that these ridges are generated via tectonic stresses within the ice shell, and manifest via either strike-slip or tensional displacement. Cycloids may have originated in response to diurnal variations in tidal stress or due to tidal stress plus additional non-synchronous and/or obliquity stresses, or conversely due to the build up of stress and periodic release through formation of tail cracks. However, it has also been shown that the tidal stresses alone are not high enough to break Europa’s ice shell. Suggestions for the genesis of fractures from the ocean or ice shell include cracks forming at the ice-ocean interface in response to either stresses from ice shell thickening, ocean overpressure, and/or dike formation propagating cracks through the shell. However, these processes may be difficult to reconcile with the presumed thick ice shell where a brittle elastic layer overlies a ductile layer that may be viscously deforming and preventing fracture. It may be that the combination of tidal and convective stresses may play a role in the formation of these features. However, with very few close flybys of Europa by Galileo, as yet no convincing evidence in any particular direction can eliminate the field of possibilities.

Europa’s bands—wide, relatively flat and linear bands of generally darker or newer ice—are regions of presumed production of new surface material, while some might be the sites of destruction of old material. Thought to be perhaps analogous to seafloor spreading centers on the Earth, these features remain incompletely understood. From where does the new material
originate? How deep do the bands penetrate into the shell? These questions require better data or new models to reconcile. Some of Europa’s bands may be responsible for reprocessing subsumed or subducted material, participating in the cycling of ice and water through the ice shell. This plate tectonic-like process, if confirmed, would represent a major step forward in understanding ice shell processes on Europa.

Europa’s enigmatic chaos terrains, including large chaos and microchaos such as pits, spots, and domes, are (thus far) unique in the solar system and as such represent a key to unraveling its geologic activity. The detailed formation mechanism for these features is debated, but all models involve formation in the presence of shallow liquid water, and thus these features are amongst Europa’s most compelling. Models exist for complete melt-through of the ice shell, however these are kinetically and thermodynamically unfavorable. Other models suggest these features form as a surface expression of various degrees of melting in the subsurface caused by diapirism, convective plumes, and/or tidal heating. These regions are relatively young, and in addition to being likely the best places to search for shallow water within Europa’s ice shell, may represent regions of surface-subsurface exchange and the production of new surface material.

Europa’s sparse cratering record and the superposition of its many and possibly recently formed surface terrain, represent the major pieces in unraveling Europa’s activity and geologic history. Ice shell processes are important to characterize in order to understand whether tidal heating, convection within the ice shell, or thermo-compositional processes are responsible for heat exchange between the ocean and ice, potentially creating a conveyor belt of material through the shell. Because the ice shell is the mediator of mixing between endogenic and exogenic processes, understanding its dynamics would result in a more complete picture of how this icy satellite has evolved through time and have implications for Europa’s habitability.

2. What is the interior structure of Europa?

Galileo gravity and magnetic field data reveal a compelling picture of Europa’s likely interior: an ice and water layer of up to ~150 km deep atop a mostly rocky interior. The induced magnetic field detected at Europa is most consistent with an ocean of similar conductivity to that of the Earth within 50 km of the surface.

However, with only 9 close flybys of Europa, both the magnetic field and gravity data are of low fidelity. For instance, the depth and thickness of the ocean layer can only be loosely constrained given assumptions about its conductivity. Gravity data are sufficient to constrain the depth of the ice-water layer to within ~50km, but are insufficient to search for topography on the sea floor, or to confirm the presence of an iron core. Moreover, if Europa has a liquid iron core, these data are insufficient to confirm an intrinsic field, only placing bounds on its maximum strength. This information is a critical part of understanding the energy budget within Europa, which would help constrain whether activity deep in its interior might be sustained until present day, perhaps powering sea floor vents or other activity that could sustain a habitable ocean.

3. What is the distribution of water within Europa?
In the search for life beyond Earth, the mantra has long been “follow the water.” On Europa, the detection of an induced magnetic field all but guarantees the existence of a liquid water ocean. However, if and how this water makes it to the surface is debated. Basal fractures, dikes, and sills could be responsible for direct communication of the ocean with the surface forming ridges or cracks, however whether these could extend through Europa’s ice shell is unclear. Many of Europa’s surface features could be formed in the presence of water, including chaos, pits, domes, and spots. While some have argued for complete disruption of the ice shell in these areas, most hypotheses involve melting within the shell via convective, tidal and/or thermo-compositional processes, rather than direct communication with the ocean. In this case ice rising from the ocean interface could be mixed with shallow ice via melting, so the distribution of water within the shallow ice is also provocative. Such features may be attractive targets for landers, and thus understanding which are water rich will be critical to future.

Geological data are inconclusive as to the depth of the ice shell. Assumptions can be grouped into two classes: thick and thin, the former with estimates ranging from ~15 to 30 km and the latter 3-5 km. This is an important constraint to have because this thickness determines, in part, where the vast majority of the immense tidal energy from Jupiter is distributed. If the ice shell is sufficiently thick, the dissipation may occur predominantly in the ice. However, interactions with ocean tides could either amplify or counteract this dissipation, thus better constraints on the ice shell, ocean, and deep interior provide a window into any endogenic activity within Europa’s silicate mantle.

Water vapor plumes have been suggested to erupt from Europa’s surface by several lines of evidence, including Europa’s variable oxygen atmosphere, interaction with the Jovian magnetosphere, its dust environment, and from telescopes. Hubble Space Telescope results suggest that variable plume activity may occur. The location of the detected plumes indicates that either ridges or perhaps chaos regions at high southern latitudes could be the source of water ejected into the Europan exosphere. This possibility is nonetheless intriguing and the ability to confirm these plumes and look for connections with surface geology would help constrain the provenance of this water.

4. What are Europa’s surface, ocean, and interior compositions?

In addition to geologic heterogeneity, Europa’s surface shows compositional diversity. Both Voyager and Galileo data showed that the surface is a mixture of dark material within the background ice, but the detailed composition remains uncertain.

Dark material is present along young ridges and their flanks and in the floors of chaos terrains, pits, and spots. These regions are possibly demonstrative of either oceanic material or reprocessed non-ice material within the shell being extruded on or concentrated in the surface. There is also a hemispheric albedo variation, with reddish material blanketing preferentially the trailing hemisphere. It is likely that the hemispheric variations are caused by interactions between surface materials and impacting high-energy particles. Galileo spectrometers suggest these darker materials are rich in magnesium, sulfur, and possibly sodium, but the results are non-unique and the conclusions vary among researchers. Earth-based telescopes suggest similar results. However, whether this represents processing of ocean material, or a mixture of exogenic
and endogenic materials, is uncertain. This material may provide clues to the habitability of Europa’s ice shell and ocean.

Based on limited magnetospheric data, Europa’s ocean composition is not well bounded, but includes a possible similarity in salinity to that of the Earth. This possibility may come as little surprise, given that the ocean water would have reacted with Europa’s silicate interior as the planet differentiated, much as water on Earth would have. However, with the constraint dependent upon the thickness of the ice and ocean, and the non-unique results regarding surface salt composition, much remains to be learned of Europa’s ocean composition. Both magnesium or sodium bearing salts are consistent with the surface spectroscopy, and this dramatically changes the ocean composition and its interactions with the sea floor. Depending on the rate of surface reprocessing and interactions between the ocean and the seafloor, Europa’s ocean could become highly acidic or basic, depending on the assumptions of the model. Thus it is critical to understand this chemistry in order to assess the moon’s dynamics and putative habitability, using both fields and direct measurements as well as modeling.

Unraveling the surface and ocean composition can also constrain the composition of Europa’s silicate interior. Is there any fundamental difference between the material that formed Europa and the presumably chondritic reservoir from which the terrestrial planets? Has the silicate mantle fully reacted with the ocean, or might such processes as serpentinization and dehydration still be underway? The structure of Europa’s mantle and core could be better constrained with more gravity science flybys, given that most of what we know is derived from a handful of Galileo passes. Determining, for instance, whether the interior is mostly hydrated, or if it is dry, would provide insight into the activity of Europa’s interior over time.

5. Is Europa habitable today? Was it ever? Has life arisen on Europa?

There are a host of interesting planetary targets for exploration. Arguably what sets Europa apart is the issue of habitability. For Europa, this can be broken down into several key components: Does Europa possess the necessary ingredients for life? If not today, did it ever? And if so, has life ever arisen on Europa? For Europa to be habitable, as we currently understand it, water and biologically relevant compounds (iron, phosphorus, nitrogen, etc) must be combined with a stable source of energy and enough time to allow for life to become established. The exact requirements are unknown, but these important considerations represent a maturing picture of what it means to be habitable. This is of course, related to but separate from whether life originates at all.

The four questions above motivate the investigation of Europa’s past and present habitability. Given its size, Europa at present likely requires a constant input of energy to maintain geologic activity that may power a biosphere. Constraints on this energy budget are likely more important for modern habitability, since its own internal heat may have been sufficient to permit habitability early on. Such activity could manifest as both surface geology and putative sea floor activity. It is likely that in order to be habitable, Europa’s surface, affected by the Jovian magnetosphere and bathed in particles from the Io torus, must be recycled on a rapid enough timescale to deliver biologically relevant oxidants and other limiting nutrients like phosphorous into the ocean. The distribution of water within Europa is important as well: too much, or too
isolated, and the necessary components for life may never be collocated or too diffuse to create
niches for life. The chemistry of the moon would regulate metabolic activity of any organisms,
and in models the possibilities for the ocean composition range from either too dilute to even
toxic.

The discussion above focuses on the habitability, keeping the question of the possible origin of
life as a separate question. Asking this question for Europa is important not only to understand
whether life ever existed there, but also to test our understanding of the origins of life on Earth.
A major focus of astrobiological research seeks to understand how planetary environments may
be geochemical precursors for life as we know it, while other work tests how life changes the
system to match its needs. Both surface and deep ocean systems are described as possible
locations for the origins of life on Earth—where surface pools of water where hydration,
dehydration, and the possible introduction of exogenic or endogenic materials creates the
conditions for life, or where hydrothermal vents in an anoxic ocean set up energetic reactions
that could build precursor geochemical systems. An origin of life on Europa, at such a great
distance from Earth, likely would represent the chance to address, in part, this debate about life’s
origins on Earth and the necessary types of systems for life to arise.

Even if Europa is presently uninhabitable, or uninhabited, it may well be that the moon once was
a stable place for life. Unique from places such as Mars where the origin of life would likely
have had to happen early, Europa may have been continuously habitable for the lifetime of the
solar system. Might there be an evolved community within or beneath the ice? The
determination of habitability gets us a step closer to answering this question, and life detection at
Europa would truly change the way we think about astrobiology, planetary science, and even life
on Earth.
Appendix A

Science Themes from Vision and Voyages

The hierarchy of science questions in this document starts with themes from 2013 Decadal Survey, “Vision and Voyages”:

A. Building new worlds:
Q1. What were the initial stages, conditions and processes of solar system formation and the nature of the interstellar matter that was incorporated?
Q2. How did the giant planets and their satellite systems accrete, and is there evidence that they migrated to new orbital positions?
Q3. What governed the accretion, supply of water, chemistry, and internal differentiation of the inner planets and the evolution of their atmospheres, and what roles did bombardment by large projectiles play?

B. Planetary habitats:
Q4. What were the primordial sources of organic matter, and where does organic synthesis continue today?
Q5. Did Mars or Venus host ancient aqueous environments conducive to early life, and is there evidence that life emerged?
Q6. Beyond Earth, are there modern habitats elsewhere in the solar system with necessary conditions, organic matter, water, energy, and nutrients to sustain life, and do organisms live there now?

C. Workings of solar systems:
Q7. How do the giant planets serve as laboratories to understand Earth, the solar system, and extrasolar planetary systems?
Q8. What solar system bodies endanger Earth’s biosphere, and what mechanisms shield it?
Q9. Can understanding the roles of physics, chemistry, geology and dynamics in driving planetary atmospheres and climates lead to a better understanding of climate change on Earth?
Q10. How have the myriad chemical and physical processes that shaped the solar system operated, interacted, and evolved over time?

Themes are followed by general target goals for the gas giants, their rings, and their moons. In this hierarchy goals are followed by target-specific objectives posed as questions and referenced to these over-arching themes and questions as Q1, Q2, etc.

At this moment in time this document is consistent with the goals of V&V, however as the next decadal survey nears themes will be re-visited and new priorities articulated.
